Biking for Health: Results of a Pilot Randomized Controlled Trial Examining the Impact of a Bicycling Intervention on Lower-Income Adults

Rebecca Bernstein, MD; Robert Schneider, PhD; Whitney Welch, PhD; Anne Dressel, PhD; Melissa DeNomie, MS; Jennifer Kusch, PhD; Mirtha Sosa, BA

ABSTRACT
Introduction: This pilot study tested the efficacy of a bicycling intervention targeting inactive, low-income, overweight adults on reducing perceived barriers to bicycling, increasing physical activity, and improving health.

Methods: A nonblinded 2-site randomized controlled trial was conducted in Milwaukee, Wisconsin, in summer 2015. Participants included members from 1 largely Latino community and a second primarily African American neighborhood. A certified bicycling instructor led a 12-week bicycling intervention. Outcome measures including biking-related attitudes, self-reported physical activity, fitness as measured by the 6-minute step test, and biometric data were collected at baseline, 12 weeks, and 20 weeks.

Results: Thirty-eight participants completed the study. Barriers to bicycling declined significantly among intervention group participants at 12 weeks with some declines persisting to 20 weeks. Bicycling for leisure or non work transportation increased significantly more in the intervention than control group from baseline to 12 weeks but this difference attenuated by 20 weeks. Both groups increased their fitness between baseline and 12 weeks, with a trend towards greater gains in the bicycling intervention group. No significant change in biometric measurements was seen at either 12 weeks or 20 weeks.

Conclusion: Despite the small study size, this bicycling intervention decreased perceived barriers to bicycling and increased bicycling activity in low-income minority participants. These findings support a larger-scale study to measure fitness and health changes from bicycling interventions.

BACKGROUND
Physical activity is inversely related to many medical conditions, particularly obesity, type 2 diabetes, and coronary heart disease—the leading cause of death in the United States. Many factors ranging from individual to environmental and cultural contribute to widespread inactivity. Further, income disparities exist in the prevalence of physical inactivity. Lifestyle activities, including bicycling for active transportation, have been found to promote healthy weight and decrease the risk of adverse cardiovascular outcomes, including mortality from cardiovascular disease.

Nationally, bicycling rates are increasing, while research suggests that lower-income and minority communities experience unique barriers to bicycling. These include lack of access to a working bicycle, bicycle theft, personal security, police harassment, safety from traffic, and cultural perceptions of bicycling as an indicator of low social status. Increasing physical activity through bicycling in low-income communities and communities of color has the potential to improve personal and public health. The previous studies of bicycling in such communities have explored barriers to bicycling or provided case study descriptions of education and encouragement programs.

Identifying successful interventions to promote physical activity in inactive adults is a critical public health need. Prior research on bicycling interventions has not specifically targeted inactive, overweight or obese lower-income adults. We are unaware of any studies utilizing a controlled trial to evaluate the impact of a bicycle training and promotion intervention using biometric and survey data collection.
We theorized that a bicycle education and promotion intervention would impact the personal attitudes and barriers towards bicycling for participants, resulting in increased bicycling activity that would lead to fitness and health improvements. Our intervention was based on the Theory of Planned Behavior\textsuperscript{13} and the Transtheoretical Model.\textsuperscript{14} A separate paper (R Schneider, et al, unpublished data, June 2016) focuses on attitudes and perceived barriers to bicycling among participants while the goals of this paper are to evaluate later stages of behavioral and health change: whether or not the bicycling intervention helped participants (1) increase bicycling and general physical activity levels, and (2) improve health, as measured by fitness testing and several biometric parameters.

**METHODS**

**Design**

The study was a 2-site, nonblinded randomized controlled trial of a bicycling intervention for inactive adults in 2 lower-income neighborhoods in Milwaukee, Wisconsin. It was reviewed and approved by the Institutional Review Board of the Medical College of Wisconsin.

**Participants**

Eligible participants were 18 to 69 years old, spoke English and/or Spanish, were currently physically inactive—as defined by self reporting physical activity less than 3 days per week for 20 minutes or more\textsuperscript{15}—and had a body mass index (BMI) ≥ 25.0. Those not meeting inclusion criteria, were currently pregnant, planning to become pregnant during the study period, or planning to relocate were excluded. Participants were screened for safety using validated physical activity readiness questionnaires\textsuperscript{16,17} and, if necessary, physician clearance. Prior ability to ride a bicycle was not required.

The study was conducted at 2 sites. One, Sixteenth Street Community Health Centers (SSCHC), is a Federally Qualified Health Center that serves a predominantly Latino community on the south side of Milwaukee. The other, Silver Spring Neighborhood Center (SSNC), is a community center located within the Westlawn Gardens public housing development, serving a predominantly African American community on the north side of Milwaukee.

**Enrollment Procedures**

Participants were recruited using flyers and at community events, with assistance from community health ambassadors. Friends or family who enrolled were randomized individually. After obtaining informed consent and confirming study eligibility, participants were randomized 1:1 to the intervention or control groups, stratified by site. Random assignments were made using Research Electronic Data Capture (REDCap). It was not possible to determine group assignment prior to randomizing each individual. Neither participants nor researchers were blinded to the group assignment. Participants in the intervention group received bicycles, locks, and helmets at baseline; control group participants received gift cards at baseline. Both groups received gift cards for attending the subsequent data collections. The control group received bicycles, locks, and helmets after completing the final data collection.

**Intervention**

The bicycling intervention included 10 scheduled group sessions at each site over a 12-week period from June to August 2015. Intervention group participants were fitted with refurbished bicycles prior to the first session. Participants were able to keep their bicycles from that point forward and were encouraged to ride independently during and after the intervention. Sessions consisted of on-road education and group rides; bicycle safety classroom instruction occurred on rain dates. Ride lengths increased progressively from 2 to 7 miles, and pace increased from 4 miles per hour (mph) to 10 mph. Participants learned about accessing local paved bicycle trails, using bike lanes, hand signaling, and navigating traffic (eg, stops, turns). Licensed cycling instructors

of the Bicycle Federation of Wisconsin administered the interven-
tion. Attempts were made throughout the study period to engage participants and resched-
ule rides at this site to increase intervention participation.

Outcome Measures
Data were collected from participants at baseline, after the 12-week intervention
concluded, and 20 weeks after baseline. Intervention group bicycles were outfitted
with cyclometers. In addition, the cycling instructors utilized structured field notes
to record observations throughout the summer. The following outcomes were
collected at each of the 3 data points: (1) self-reported bicycling, perceived barriers
to bicycling, and overall activity; (2) fitness; and (3) biometrics.

Self-reported bicycling, perceived bar-
riers to bicycling, and overall activ-
ity – The International Physical Activity
Questionnaire (IPAQ) longform, a pre-
viously validated tool, provided estimates
of weekly physical activity within specific
domains, including transportation and leis-
ure. It was self-administered or interviewer-
administered, at the preference of each
participant. A Bicycle Attitudes Survey
developed by the research team asked about
bicycling activity and 19 possible barriers to
bicycling. The ordinal response options for
each barrier were “does not apply” (scored
as 0), “not significant at all” (scored as 0),
“somewhat significant” (scored as 1), “very
significant” (scored as 2), and “so significant
that it keeps me from riding” (scored as 3).
We measured the change in perceived barri-
ers by comparing the score at baseline with the score at 12 weeks or
20 weeks. Additional detail about this survey is available elsewhere
(R Schneider, et al, unpublished data, June 2016). Both surveys
were available in English and Spanish.

Fitness – The 6-minute step test,19 a convenient and validated
variation on the 6-minute walk test,20 was used as a maximal exer-
sion fitness test. Participants were instructed to step up and down
a 20-centimeter step as many times as possible in 6 minutes, while
the number of steps was recorded.

Biometrics – Baseline height and weight were collected, and
weight was remeasured at 12 and 20 weeks; body mass index
(BMI) was calculated; waist circumference was measured. Blood
pressure was measured manually after participants sat quietly for
5 minutes; the average of 2 readings was used for each time point.
**RESULTS**

**Participant Characteristics**

The participants were predominantly female (84%) and middle-aged (mean 41.8 years, range 22-65 years). Ninety-four percent of participants at the SSCHC site were Hispanic/Latino ethnicity and 100% of participants at the SSNC site were African American. Participants at both sites had low socioeconomic status, with 53% of participants overall reporting annual incomes of less than $15,000 and 100% of participants at the SSNC site were African American.

**Data Analysis**

Participant characteristics were summarized using descriptive statistics. Tests for baseline differences between groups were assessed using t-tests for continuous variables, chi-square Fisher exact testing for proportions and categorical variables, and exact Wilcoxon rank-sum test for ordinal variables. Two-sample paired t-tests were used to identify significant changes in bicycle activity, fitness, and biometric measures between the bicycling intervention and control groups from baseline to 12 weeks and baseline to 20 weeks (STATA 14.1, College Station, TX). IPAQ was scored per established scoring protocol, utilizing minutes/day as the outcome.

**Physical Activity**

The analysis explored overall self-reported physical activity. However, upon initial tabulation at baseline, on average, participants reported 270.5 minutes/day of vigorous intensity activity and 467 minutes/day of moderate intensity activity. Therefore, standard IPAQ scoring procedures were followed excluding participants reporting outlying values (>960 minutes/day of activity). Six participants’ data were excluded from vigorous intensity analysis and 12 participants were excluded from moderate intensity analyses. Many of the outlying values were reported in the occupation and household activity sections; therefore, only transportation and leisure time activity data are presented, as those are of interest to the current study.

Responses from the IPAQ revealed a significant difference in time spent bicycling for transport between control and intervention groups (mean difference +8.8 minutes/day in intervention group [95% CI, +0.2-17.4]) at the 20-week follow-up. Additionally, there was a significant increase in time spent biking in the intervention group from baseline to 20 weeks (+8.5 min/d, 95% CI, +1.3-15.8), with no significant increase in biking time in the control group.

*The reported P-value evaluates the change in the number of days in the previous week that the respondent reported bicycling for a given purpose relative to the baseline survey; P-value less than 0.05 indicates that intervention group participants reported significantly greater increases in bicycling frequency than the control group participants.

**Barriers to Bicycling**

Several barriers reported at baseline declined significantly more among intervention group members than control group members. At 12 weeks these barriers included not feeling healthy enough to bike (P = 0.036), being physically uncomfortable while bicycling (P = 0.012), not having a bicycle to use (P = 0.043), not having other people to bike with (P = 0.031), not knowing routes to use (P = 0.039), not feeling safe from crime (P = 0.020), not feeling safe from car traffic (P = 0.015), and adult bicycling not being socially acceptable in the respondent’s neighborhood (P = 0.049). Two of these barrier reductions remained significantly greater for the intervention group at 20 weeks: not feeling healthy enough to bike (P = 0.045) and not feeling safe from car traffic (P = 0.015). Reductions in perceived barriers to bicycling are discussed in more detail elsewhere (R Schneider, et al, unpublished data, June 2016).
Further, time spent in moderate intensity leisure time physical activity was significantly different between groups at 12 weeks (mean difference +2.6 minutes/day in intervention group (95% CI, +0.8-6.0). There were no significant differences between or within groups for time spent in moderate intensity leisure time activity.

Self-reported bicycling for specific purposes also was compared between groups (Table 2). Bicycling for leisure and for non-work-related transportation both increased significantly more in the intervention than the control group (P=0.020 and P=0.019, respectively) from baseline to 12 weeks, while there was no significant difference between groups in bicycling to work (P=0.751). None of these differences between groups persisted at 20 weeks.

Cyclometer data were available for 9 intervention group participants and reflected 23 to 72 days of data. These participants attended between 2 and 6 group rides and averaged 6.5 miles per week (range 1.0-15.0 miles per week), for a total recorded average riding distance of 38.6 miles (range 8.0-114.0 miles).

**Fitness and Biometric Measures**

Participants did an average of 124.3 steps on the baseline step test (95% CI, 116.0-132.6). The intervention group did an average of 128.4 (95% CI, 115.7-141.1) steps at baseline compared to 120.1 (95% CI, 108.2-132.0) in the control group; this difference was not statistically significant (P = 0.15).

Amongst baseline participants who remained in the study at 12 and 20 weeks, the group as a whole increased number of steps from 126.4 (95% CI, 117.3-135.5) to 138.5 (95% CI, 126.1-150.8) from baseline to 12 weeks (n=20, P = 0.011). BMI, waist circumference, and blood pressure did not change from baseline to 12 weeks for the group as a whole.

We compared the change in steps from baseline to 12 weeks and 20 weeks between intervention and control groups. There was a trend toward individuals in the intervention group having a greater increase in steps from baseline to 12 weeks by +13 steps (95% CI, +1.2 to +24.8) versus +11.1 steps in the control group (95% CI, -2.85 to +25.0), but this difference was not statistically significant. Both groups demonstrated some regression in fitness after the intervention period and summer months ended, with average number of steps trending back down between 12 and 20 weeks, from 136.6 to 125.1 in the control group and 145.2 to 140.4 in the intervention group; the change in steps from 12 to 20 weeks was nonsignificant (P = 0.076).

At baseline, average BMI was 36.6 (95% CI, 25.5-51.2) and waist circumference was 105.7 cm (95% CI, 72.5-136.5). Baseline average systolic blood pressure was 123.9 (95% CI, 95.3-147.0) and diastolic blood pressure was 77.5 (63.5-93.0). Baseline biometric measurements did not differ between study groups. BMI, blood pressure, and waist circumference did not change significantly between study groups throughout the study period. See Table 3 for additional biometric measurement data.

**DISCUSSION**

Our study generally supports the feasibility of conducting a bicycling intervention to improve the health of lower-income over-
weight or obese adults in urban communities of color. Intervention group participants experienced greater reductions in perceived barriers to bicycling and reported bicycling more for leisure and nonwork transportation purposes than control group participants.

There was interest in our target communities to recruit participants to the study. Our gender imbalance was notable; typically, bicycling is more common for adult men than women.\textsuperscript{21} However, our recruitment tended to center around community events and health-related programming better attended by women. The implementation success of this intervention was highly discordant at the 2 sites. This led to smaller than expected sample size and dilution of the program effect, as the SSNC intervention participants each attended only 1 ride compared to the more robust intervention received by the 9 SSCHC intervention participants. Some possible factors include a more consistent ride schedule at SSCHC, a female cycling instructor (like the majority of participants), childcare availability, and different participant demographics.

However, the success of our SSCHC site intervention was notable. Participant engagement was high and bicycling skills, endurance, and comfort increased dramatically for active participants. Based on the success of our SSCHC site intervention implementation, we feel this program is feasible, with attention to the factors described above. Based on our pilot findings, we offer several recommendations for improvement and scaling for a larger study (see Table 4).

Our pilot experience supported our general approach to data collection, particularly the use of the step test, biometric assessments, and Bicycle Attitudes Survey. Even though IPAQ is widely used, validated for use in many languages and populations, and highly accepted for physical activity measurement, there are a number of documented limitations. Specific to our population, there is a well-documented overreporting of nonleisure time moderate to vigorous physical activity (MVPA) in multicultural samples or among cultural samples with higher levels of labor-based occupations.\textsuperscript{22} Despite the availability of print and interviewer-administered IPAQ surveys in participants’ preferred language, our participants appear to have overestimated their physical activity, as evidenced by the many participants reporting outlier activity levels. Direct measurement of physical activity would be preferable, although reliable capture of bicycling can be challenging.\textsuperscript{23}

This pilot study was the first of its kind to test a bicycling intervention in a community-based setting using a randomized study design. Implementing this rigorous study design within community settings posed challenges, including regular participation, comprehension of technical survey questions, and social groupings.\textsuperscript{24} However, its findings support additional research to refine bicycle program implementation and research methods in order to gain more knowledge about the potential impact of bicycling to improve the health of lower-income urban communities.

In addition to the sample size and variable intervention implementation discussed above, the study has additional limitations.

We recruited and enrolled participants who were family members or friends, but randomized them individually. When pairs were randomized to the intervention, they were observed to ride together frequently between group sessions. This finding is concordant with prior studies showing social support is an important facilitator of bicycling.\textsuperscript{25} Our sample size was not adequate to consider recruiting and analyzing for this clustering effect. Another potential limitation results from the high proportion of participants without a bicycle at the beginning of the study. This instrumental barrier essentially prevented bicycling in the control group, which may have limited the usefulness of other information provided about barriers to bicycling. However, our experience was that the additional support and education provided by the intervention was necessary. Several of the intervention participants who were given access to their own bicycles either did not claim them or did not use them. Finally, our findings may not be applicable to other lower-income overweight urban populations, as we have identified that many cultural, structural, and other factors impact interest in and participation in bicycling.

Despite these limitations, this pilot study was the first of its kind to test a bicycling intervention in a community-based setting using a...
randomized study design. Its findings support additional research to refine bicycle program implementation and research methods in order to gain more knowledge about the potential impact of bicycling as a feasible modality to improve the health of lower-income communities.
